Compendium to "A Tutorial for Quantifying Within- and Between-Participant Variance in Multilevel Logistic Models"

Sean Devine, A. Ross Otto, James O. Uanhoro, Jessica Kay Flake

2022-10-11

What is this?

This is a companion piece for "A Tutorial for Quantifying Within- and Between-Participant Variance in Multilevel Logistic Models" (**PUBLICATION LINK**), which contains all the code (code boxes and other miscalenous analyses) used in the paper.

The goal of this document is to present all of the techniques presented in the paper in a reproducible and easy to follow manner. Throughout this compendium, we will refer to R functions. We assume readers are familiar with the basics of R syntax and some basic functionality, but will do our best to remain as clear as possible if they are not. This document is meant to be read *alongside* the original paper. We will not go into as much detail about the concepts being presented and, as such, urge readers to use this as a supplement to the original paper, rather than a wholly complete tutorial in its own right.

This document will proceed in the same order as the original paper and will include all of the same code and data. Specifically:

- 1. Loading and cleaning the data.
- 2. Fitting and summarizing logistic MLMO.
- 3. Reproducing Figure 2 in the paper.
- 4. Computing the ICC using
 - a. The Latent Threshold approach
 - b. The Simulation approach
 - c. The Linearization approach
 - d. The Median Odds Ratio
- 5. Bootstrapping procedures
- 6. Computing the ICC with a model that contains predictors.
- 7. Supplemental Materials
 - a. Linear regression of response times.
 - b. Multilevel linear regression of response times.
 - c. Reproduce Figure S1.

Loading and cleaning the data

- Line 1. The data is loaded from a .csv file provided on the OSF page for Bogdanov et al. (2022)¹. This is done with the read.csv() function that is built-in to R.
- Line 2. We then subset the data such that data.Ctl only contains data from participants in the control condition.
- Line 3. Finally, we reverse-code the effort_choice variable to make it more interpretable, such that 0 refers to low effort choices and 1 refers to high effort choices.

¹https://osf.io/26w4u/

```
data <- read.csv('Bogdanovetal2021/DST_data_osf2.csv')
data.Ctl <- data[data$condition=='control', ] # focus just on control condition
data.Ctl$effort_choice <- abs(data.Ctl$effort_choice-1)
```

Fitting and summarizing logistic_MLMO.

Next, we fit logisticMLMO from the paper. As a reminder, this is the null model on which the variance parameters were estimated throughout the text.

- Lines 1-4. We load the lme4 package. If you do not have it installed already, run install.packages('lme4') to do so.
- Line 7. Now we can fit the model described in the text. To do so, we use the glmer() function from lme4. The first variable before the ~ is the binary outcome variable, effort_choice in our case. After the ~, we input the predictor variables, which in this case is just the intercept, designated by a 1. Finally, we specify the random effects and grouping variable. Here, we only estimate random intercepts, hence we input a 1 before the | followed by the grouping factor, which here is PID. We then specify the data to be used, using the data=data.Ctl argument, and finally specify the distribution to be used, which in this case is the binomial distribution. For more information on lme4 syntax in R, see https://www.learn-mlms.com/.
- Line 10. We then output the summary of the model to the console.

```
# if the lme4 is not installed, run this command first:
# install.packages('lme4')

library(lme4)

# Fit an intercept only model of choice
logistic_MLMO <- glmer(effort_choice ~ 1 + (1|PID), data=data.Ctl, family='binomial')

# print summary statistics of this model
summary(logistic_MLMO)</pre>
```

As described in the text, the grand average intercept (γ_{00}) is -0.34, which represents the average log-odds of choosing the high-demand option. This can be converted into a probability as follows:

```
P(\text{Choose High Demand}) = \frac{\exp(-0.34)}{1+\exp(-0.34)} = 0.42.
```

In R, we can do this computation this as follows:

- Line 1: Extract the fixed effects from logistic_MLMO using the fixef function from lme4. Since this is a null model, the only fixed effect is the grand intercept (γ_{00}) .
- Line 2: Convert this to a probability using Eq. 2-3 in the main paper.
- Line 3. Print this estimate to the console.

```
gamma_00 = fixef(logistic_MLM0)
pChooseHighEffort <- exp(gamma_00)/(1+exp(gamma_00))
cat('estimated group average probability of choosing the high-effort cue = ', pChooseHighEffort, '\n')</pre>
```

estimated group average probability of choosing the high-effort cue = 0.4173215

Reproducing Figure 2 in the paper

To reproduce Figure 2 in the paper, we will extract the estimated demand preferences (in log odds) per participant in the DST. These estimates are also known as "empirical Bayes' estimates", hence we will store these in a variable called eb.

```
# extract random intercepts from model and add them to the fixed effect (gamma00)
eb <- coef(logistic_MLM0)$PID
head(eb)</pre>
```

```
## (Intercept)
## 1 -1.35734356
## 2 -0.28074761
## 3 -0.03893175
## 4 -0.03199605
## 5 0.77900510
## 6 -0.42353287
```

Next, we extract the variance around the intercept (τ_0^2) using the VarCorr function from lme4\$. The syntax here is a little convoluted. The VarCorr command extracts the random variance components from a fitted model (here logistic_MLMO). Alone, this yields a variance component per grouping variable and per number of random variance parameters specified in the model $(\tau_0^2, \tau_1^2, \text{ etc.})$. In our case, we have one grouping variable, PID, and so we specify that we are interested in this the random intercept variance for this group using \$PID[1].

```
# extract the estimated random intercept variance (tau^2_0)
tau <- VarCorr(logistic_MLM0)$PID[1]</pre>
```

Finally, we visualize this distribution in a histogram and overal an estimated normal density curve with $\mu = \gamma_{00}$ and $\sigma = \sqrt{\tau_0^2}$. The specific steps taken here are not of critical importance to the topic of this tutorial, as they mainly involve plotting commands in base R. If this section is confusing for readers and they wish to be able to follow along better, we suggest this introductory website that explains basic visualization techniques inherent to R: https://bookdown.org/rdpeng/exdata/the-base-plotting-system-1.html.

```
# plot the histogram of the random intercepts and overlay an estimated normal density curve with # mu = gamma00 and sd = sqrt(tau^2_0)
```

```
hist(eb[[1]], main='', xlab=expression(gamma[`00`] + U[`0j`]), freq = F, xlim=c(-3,3), ylim=c(0,1))

curve(dnorm(x, fixef(logistic_MLMO), sqrt(tau)), add=T, lwd=2)

# finally, shade in areas of demand-avoidance (b0 < 0) and demand-seeking respectively (b0 > 0)

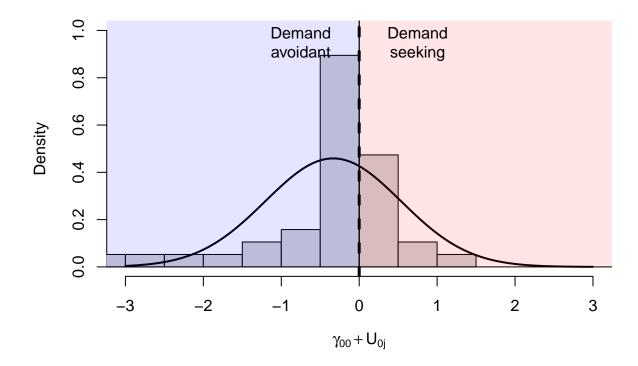

abline(v=0, lty='dashed', lwd=3)

rect(0, 0, 10, 100, col = scales::alpha('red', .1))

rect(0, 0, -10, 100, col = scales::alpha('blue', .1))

text(-.75, .95, labels = 'Demand\navoidant')

text(.75, .95, labels = 'Demand\nseeking')
```

Computing the ICC

Latent Threshold Method

- Line 1. We extract the random intercept variance (τ_0^2) using the VarCorr command (see explanation above).
- Line 2. We specify the within-subjects (residual) variance to be $\sigma^2 = \frac{\pi^2}{3}$.
- Line 3 and on. We compute the ICC using the following equation $\frac{\tau_0^2}{\tau_0^2 + \sigma^2}$ and print this output to the console.

```
tau20 <- VarCorr(logistic_MLM0)$PID[1]
sigma2 <- pi^2/3
threshICC <- tau20/(tau20+sigma2)
```

```
# print result
cat('ICC using the Latent Threshold Approach = ',threshICC,'\n')
```

ICC using the Latent Threshold Approach = 0.1867374

Simulation Method

The simulation method requires multiple steps.

- Line 1. First, we set a seed for reproducibility. This ensures that the subsequent results will replicate on any device that runs this code.
- Line 2. We extract the the random intercept variance using VarCorr.
- Line 3. We extract the grand intercept (γ_{00}) using fixef (see explanation above).
- Line 4. We set a large number of simulations to execute (here 1e5or 100 000). We call this variable M.

```
set.seed(2022) # for reproducibility
tau20 <- VarCorr(logistic_MLMO)$PID[1]
gamma00 <- fixef(logistic_MLMO)[[1]]
M <- 1e5</pre>
```

Next, we simulate the random effects from M draws and store these values in a variable called UOj. Note. we take the square root of τ_0^2 because rnorm() requires the standard deviation, not the variance.

```
U0j <- rnorm(M, 0, sqrt(tau20))</pre>
```

We then compute the expected probability (in log odds) of choosing the high demand option on each draw. Because logisticMLM_0 has no predictors, this is computed simply as the grand intercept (γ_{00}) plus the random deviations from this intercept we simulated in the previous step. This is then converted into a probability (using Eq. 2-3 from the paper).

- Line 1. Compute the expected probability in log odds.
- Line 2. Convert this to probabilities.

```
logit_p_hat <- gamma00+U0j
p_hat <- exp(logit_p_hat)/(1+exp(logit_p_hat))</pre>
```

We can then compute the level 1 variance using the equation for the Bernoulli variance: $var = \hat{p} * (1 - \hat{p})$ (see main paper).

```
var_L1 <- p_hat*(1-p_hat)</pre>
```

Finally, we compute the ICC in the traditional way, taking the average level 1 variance as σ^2 and the variance of the predicted probabilities from each simulation \hat{p} as τ_0^2

- Line 1. Compute σ^2
- Line 2. Compute the ICC.
- Line 3 and on. Print the result to console.

```
sigma2 <- mean(var_L1)
simICC <- var(p_hat)/(var(p_hat) + sigma2)

# print result
cat('ICC using the Simulation Model = ',simICC,'\n')</pre>
```

ICC using the Simulation Model = 0.1390484

Linearization Method

The linearization method also proceeds in a series of steps.

First, τ_0^2 and γ_{00} are extract from logistic_MLMO using VarCorr and fixef as we have done above.

```
tau20 <- VarCorr(logistic_MLMO)$PID[1]
gamma00 <- fixef(logistic_MLMO)[[1]]</pre>
```

Next, we evaluate the probability of success at the mean of random effects (i.e., at the fixed effect, γ_{00}).

```
p <- exp(gamma00)/(1+exp(gamma00))
```

We then compute the Bernouilli variance of this fixed estimate and store this value in a variable called var1.

```
var1 <- p*(1-p)
```

Next, we compute the variance in the level-1 outcome using the linearized equation provided in the main text. We store this in a variable called var2.

```
var2 <- tau20*p^2*(1 + exp(gamma00))^(-2)
```

Finally, with these values in hand, we compute the ICC, taking var2 as our measure of between-person variance, τ_0^2 , and var1 as our measure of within-person variance, σ^2 , and print the result of this computation to the console.

```
linICC <- var2/(var1+var2)

# print result
cat('ICC using the Linearization method = ',linICC,'\n')</pre>
```

ICC using the Linearization method = 0.1551821

Median Odds Ratio

The MOR is straightforward to compute.

- Line 1. Extract the random intercept variance from the model using VarCorr.
- Line 2. Compute the 75th percentile of the cumulative distribution function of a standard normal distribution. In R, this can be done using the qnorm function and specifying the percentile (here 0.75).
- Line 3 and on. Compute the MOR as: $MOR = \exp\left(\sqrt{2\tau_0^2}\phi(0.75)\right)$. Print this value to console.

```
tau20 <- VarCorr(logistic_MLMO)$PID[1]
phi75 <- qnorm(.75) # 75th percentile of normal CDF
MOR <- exp(sqrt(2*tau20)*phi75)

cat('Median Odds Ratio = ',MOR,'\n')</pre>
```

Median Odds Ratio = 2.291137

Bootstrapping

Below we provide two bootstrapping techniques. First, we describe how to implement the bootstrapping procedure using the functions we provide alongside the paper. These functions are meant to be simple to implement, without the need for complex code that involves loops and storage. That being said, some readers may be interested in understanding this process. Accordingly, we provide a fully-worked example that goes through such a process.

Bootstrapping using provided functions

To utilize the function calls stored in fx.R, we first have to source them using the source() function from R.

```
source('fx.R')
```

Once this is done, we should have access to all of the custom functions provided in fx.R. Of interest to us here are those used for bootstrapping. Specifically, bootstrap_icc. This function takes the following arguments:

- fit: The fitted model
- gr : he grouping variable (in our case, PID)
- method: The method to use: icc_thr (Threshold method), icc_sim (Simulation method), icc_lin (Linearization method), MOR (MOR).
- B: The number of samples to produce.
- seed: The random seed to use.

As an example, we can compute 100 bootstraps of the ICC using the latent threshold method as follows. We can the print out these bootstrapped values.

Note: This can take a few moments.

```
bootstrap_thr <- bootstrap_icc(logistic_MLMO, gr='PID', method='icc_thr', B = 100, seed = 2022)
```

```
bootstrap_thr
```

##
   [97] 0.14468275 0.14297011 0.21971101 0.18426185
```

Using the built-in quantile function in R, we can then compute 95% confidence intervals based on these bootstrapped estimates.

```
quantile(bootstrap_thr, c(.025, .975))
```

```
## 2.5% 97.5%
## 0.1089664 0.2576925
```

For completeness, we illustrate the same syntax for bootstrapping estimates using the other methods described above, but do not run this code for time purposes.

```
bootstrap_sim <- bootstrap_icc(logistic_MLMO, gr='PID', method='icc_sim', B = 100, seed = 2022)
quantile(bootstrap_sim, c(.025, .975))</pre>
```

```
bootstrap_lin <- bootstrap_icc(logistic_MLMO, gr='PID', method='icc_lin', B = 100, seed = 2022)
quantile(bootstrap_lin, c(.025, .975))

bootstrap_MOR <- bootstrap_icc(logistic_MLMO, gr='PID', method='MOR', B = 100, seed = 2022)
quantile(bootstrap_MOR, c(.025, .975))</pre>
```

Bootstrapping "by-hand"

41

Below we provide commented code to estimate bootstrapped samples "by-hand" for readers who are interested. We will not comment on this in depth, as it is outside the scope of the tutorial and we provide functions to accomplish the same effect, but interested readers are welcome to explore the code below.

```
# 0. Set constants for bootstrapping procedure
   В
            <- 1000
                                           # number of bootstraps
2
            <- logistic_MLMO@frame$PID # extract id vector from model data</pre>
   ids
3
            <- length(unique(ids))</pre>
                                           # number of clusters (subjects)
   nTrials <- table(ids)</pre>
                                           # number of trials per subject
            <- VarCorr(logistic_MLMO)$PID[1]</pre>
   tau20
   g00
            <- fixef(logistic_MLMO)[[1]]</pre>
   output <- matrix(NA, B, 7, dimnames = list(NULL, c('iteration', 'threshICC', 'simICC', 'linICC', 'MOR'</pre>
   # 1. Cycle through iterations (i) of bootstrapped samples
10
   for(i in 1:B) {
11
      if(i%100==0) cat('bootstrapping is', round(i/B,2)*100, '% complete.')
      # 1.1 Simulate data
13
                     <- rnorm(K, 0, tau20)</pre>
                                                      # random deviations per subject
      U0j
14
      LOR_j
                     <- g00 + U0j
                                                      # log odds of response==1 per subject
15
                     <- exp(LOR j)/(1+exp(LOR j)) # convert LOR to probability</pre>
      p_j

```

Computing the ICC with a model that contains predictors

We will fit a model that predicts effort choice as a function of trial number (see main text for more details).

First, we will compute a block-wise trial number estimate, since one was not provided in the main text. The details here are not very important for readers unfamiliar with loops in R. All you need to know is that the final output is a vector of increasing integers that represent the trial number within a block of the DST, which is called trial in the dataframe, data.Ctl.

```
data.Ctl = data.Ctl[order(c(data.Ctl$PID, data.Ctl$block)),]
data.Ctl = data.Ctl[!is.na(data.Ctl$PID),]

trial = c()
for(i in unique(data.Ctl$PID)) {
  for(j in unique(data.Ctl$block)) {
    trial = c(trial, 1:nrow(data.Ctl$PID==i & data.Ctl$block==j,]))
}
}
data.Ctl$trial=trial
```

Once these values are computed, we can model these data using the same glmer syntax described at the beginning of this document.

- Line 1. First, we centre trial number at its median. This is accomplished by simply substracting the median trial number (37) from each trial number in the vector. This guarantees that the intercept of the resultant model will represent the average probability (in log odds) of choosing the high-effort option at the middle trial of a block. We store these centred trial numbers in a vector called trial_c.
- Line 2. We will also scale this newly centred trial numbers, trial_c to be between 0 and 1. This is necessary because glmer will sometimes run into issues when predictors are too large in magnitude.

```
data.Ctl$trial_c = data.Ctl$trial - median(data.Ctl$trial)
data.Ctl$trial0 = data.Ctl$trial_c/max(data.Ctl$trial_c)
```

Having done this, we can fit the model below. Again, if this syntax is confusing to readers, visit https://www.learn-mlms.com/.

```
logistic_MLM1 = glmer(effort_choice ~ trial0 + (1|PID), data=data.Ctl, family='binomial')
summary(logistic_MLM1)
```

```

icc_lin(logistic_MLM1, 'PID')

## [1] 0.1558737

MOR(logistic_MLM1, 'PID')

## [1] 2.296285
```

Supplemental Materials

For the examples here, we will predict participants' response times during the DST (TS_RT) from whether the previous trial was the same decision rule as the previous trial (Switch).

Linear regression of response times

In R, we can compute a linear regression using the lm() command.

- Line 1. We predict the time it takes to respond from Switch. The outcome variable, TS_RT is placed before the ~ and the predictor, Switch is placed after.
- Line 2. We then print the summary of this model.
- Line 3. We print the residual variance, σ^2 of this model. Note: the sigma function return the standard deviation, which we then square to obtain σ^2 .

```
linear_regression <- lm(TS_RT ~ Switch, data=data.Ctl)</pre>
print(summary(linear_regression))
##
## Call:
## lm(formula = TS_RT ~ Switch, data = data.Ctl)
##

cat('The residual variance (sigma^2) of the linear regession equals', sigma(linear_regression)^2, '\n')
```

Multilevel linear regression of response times

To fit a multilevel form of the regression above, we use the lmer function from the lme4 package.

The residual variance (sigma^2) of the linear regession equals 1.045302

- Line 1. We fit the multilevel model using similar syntax to lm. The only difference is that we include a term for the random effects, where we specify we want random intercepts (1) per (1) participant (PID).
- Line 2. We then extract the random intercept variance, τ_0^2 using VarCorr (see above for explanation).
- Line 3. Unlike a logistic multilevel model, linear multilevel models have an estimated residual standard deviation term, which can be extracted using the sigma function and squared to produce the residual variance, σ².
- Line 4 and on. The ICC can be computed as: $ICC = \frac{\tau_0^2}{\tau_0^2 + \sigma^2}$. The summary of the model can then printed, along with the ICC.

```
linear MLM <- lmer(TS RT ~ Switch + (1|PID), data=data.Ctl)</pre>
            <- VarCorr(linear_MLM)$PID[1]</pre>
sigma2
            <- sigma(linear MLM)^2</pre>
            <- tau20/(tau20+sigma2)</pre>
print(summary(linear_MLM))

The ICC for the linear MLM is 0.1175482

Reproduce Figure S1

The steps to reproduce Figure S1 are more or less the same as to reproduce Figure 2. As such, we suggest readers read that section again to understand below. Again, if any of the visualization steps are unclear, we point readers to https://bookdown.org/rdpeng/exdata/the-base-plotting-system-1.html.

```
1  U0js <- coef(linear_MLM)$PID[,1]
2  g00 <- fixef(linear_MLM)[1]
3  hist(U0js, xlab = expression(gamma['00']+U['0j']), ylab='Number of Particpants', main='')
4  abline(v=g00, col='red', lty=2, lwd=2)
5  legend('topright', bty='n', col='red', lty=2, lwd=2, legend=expression(gamma['00']))</pre>
```
